Choice of protection

PAGE 15

The protection of structures subject to the risk of earthquakes only really began in the middle of the 20th century.

In the majority of cases, structures used passive protection such as shear walls in buildings or even protection based on the plastification of elements chosen in advance for bridges. Even though this type of protection allows the structures to resist design earthquakes and ensure the protection of human lives, after a high-intensity earthquake it often meant major repairs to the damaged protective elements.

Modern society no longer accepts that the consequences of earthquakes are inevitable and the current trend is to equip structures in seismic zones with special devices that absorb or limit the effects of earthquakes on structures. This is positive protection.

Using its involvement and experience in the field of construction and works equipment, Freyssinet has contributed to the development of these seismic devices and today offers a complete range of special products called TRANSPEC®.

These devices can be used alone or in combination to achieve the most efficient and suitable protection for the project. This protection is based on the three fundamental operational modes, namely: **isolation, connection, dissipation**.

Passive protection

Deck subjected to the earthquake
(not equipped with seismic devices)

Positive protection

Deck subjected to the earthquake
(equipped with seismic devices)

The Freyssinet solutions

Isolation

The principle involves isolating the structure from the movement of the ground by using flexible connectors, mainly structural elastomeric bearings or sliding devices, to increase the natural period of the structure to protect it from, and reduce the response to, the seismic acceleration. This results in a reduction of the acceleration of the structures thus equipped by a factor of 2 or 3.

The efficiency of the isolators is directly linked to the transverse rigidity of the structural bearings and leads to significant movements of the structure during the earthquake.

The effect of the isolation of the structure can therefore be seen in the low natural frequency, slow acceleration and significant relative movements.

Connection

It may be advantageous to limit the seismic movement of the structures to simplify the equipment linking them to neighbouring structures (expansion joints, etc.).

In these cases the designer will use either mechanical structural bearings to transmit directly and in totality the service and seismic loads from the foundations to the structures (passive protection), or seismic connectors. Seismic connectors have the characteristic of only providing very low resistance to slow movements such as those due to temperature and stress-strain variations. In contrast, they provide a rigid link between the superstructure and its supports during rapid movements such as those caused by seismic events.

Another advantage of connectors is the distribution of the major seismic horizontal forces between all the supports (piers) where installed.

Dissipation of energy

The energy developed by earthquakes may be dissipated using dampers to reduce their effects on the protected structures. In the same way as the connectors, the dampers only provide very low resistance to slow movements but are completely efficient during rapid movements (earthquakes, collision fenders, etc.).

These dampers are generally used together with an isolation, produced for example by structural elastomeric bearings, to reduce the movement of structures while limiting the forces to which they are subjected.

Dampers very significantly reduce the overall repair cost of the structures and keep them functional after an earthquake, this is particularly critical in, for example, hospitals where an immediate return to full functionality is essential. They also efficiently protect existing structures which were not originally designed to withstand seismic activity.

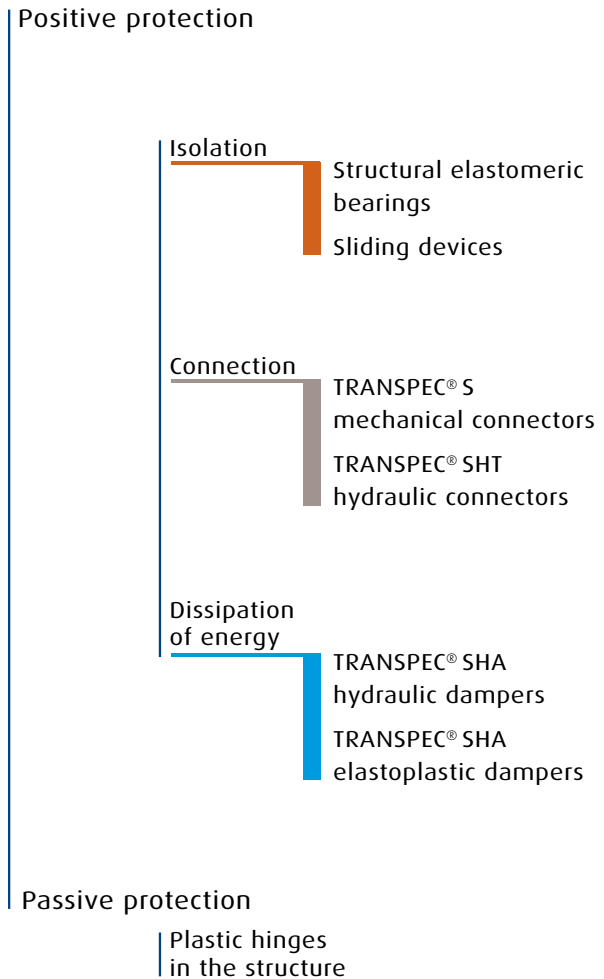

Seismic devices: The Freyssinet solutions

The choice of protective devices depends on various parameters: the seismic level of the site, the type and characteristics of the protected structure and the maximum response allowed.

The objective in terms of protection is achieved by fitting the structure with one or more types of device depending on the options taken:

Seismic devices

Positive protection: Isolation /

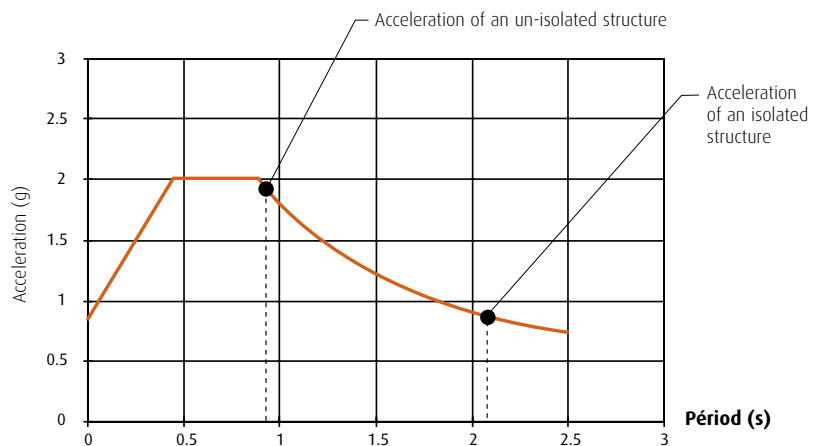

Elastomeric bearing

Structural elastomeric bearings

Isolation achieved with structural elastomeric bearings consists of increasing the natural period of the structure by extending the dominant values liable to be produced under the seismic activity. The isolation is characterised by a reduction in seismic forces.

The seismic isolators are particularly suited to massive, circular structures such as liquefied gas reservoirs and nuclear power stations and act as lateral springs which re-centre the structure after an earthquake. They also have an internal damping capability which gives them an energy absorption capacity which can be augmented by TRANSPEC® SHA dampers.

Spectral response of an isolated structure

Sliding devices

These devices make almost perfect isolators. They are usually used in combination with lateral springs (e.g. structural elastomeric bearings) whose function is to limit overall movement during the earthquake and to return the structure to its original position.

Controlled friction devices, i.e. between a μ_{min} value and a μ_{max} value, limit structure accelerations to the $\mu_{max}.g$ value while the ground acceleration less than $\mu_{min}.g$ will be filtered by the elastic function of the structural elastomeric bearings.

Furthermore, it is important to construct sliding devices that guarantee sufficient friction to dissipate enough seismic energy and to reduce movements of the structure subject to the earthquake whilst maintaining

Connection

an acceptable acceleration level. This was the option taken by Freyssinet when providing 20% nominal friction elasto-sliding devices for the protection of nuclear power stations which guarantee nominal maximum acceleration of 0.2g.

Connectors

These devices react according to the speed of movement involved and act as "safety belts": During slow movements, due to temperature variations, the connectors only provide very low resistance. However, in the event of rapid movements caused by an earthquake, the connectors are blocked and create a rigid connection between the structure and its supports. They thus transfer all the horizontal seismic forces.

Freyssinet offers two connector models:

- TRANSPEC® S mechanical connector
- TRANSPEC® SHT hydraulic connector

Static diagram

Elements not under stress in grey

Dynamic diagram

Elements under stress in orange

Advantages:

- Transfer of high-intensity loads
- Movements limited to the deformation of substructure in the event of an earthquake.
- Distribution of the horizontal seismic forces to all piles provided.
- Simplification of equipment (structural bearings and expansion joints).

Positive protection: Connection

TRANSPEC® S

TRANSPEC® S mechanical connector

The TRANSPEC® S mechanical connector (patented system) comprises an anchor block through which runs a steel bar. The ends of this bar are supported by the structure to be connected while the anchor block is connected to its supports. Specially designed partner pilot jacks follow the movement of the bar in slow structural movements. When a rapid stress acts on the TRANSPEC® S, these devices act as a gate and block the bar, and thus the structure, with the wedges. If the movement is reversed, the TRANSPEC® S reacts in the opposite direction.

The advantages of TRANSPEC® S are:

- Compactness and robustness.
- Less maintenance.
- Ease of installation.

Tests have shown the remarkable efficiency of TRANSPEC® S and verified its behavioural principle.

Bearing in mind their small size, TRANSPEC® S can be connected to a guided sliding cylinder support device to form a compact set called DYNATRON.

DYNATRON

Positive Protection: Connection

TRANSPEC® SHT hydraulic connector

The TRANSPEC® SHT hydraulic connector comprises a cylinder filled with a special fluid in which a rod with a piston moves. A valve with a calibrated opening allows for communication between the two internal chambers separated by the piston. When the rod moves, the fluid moves freely from one chamber to the other. In the event of a rapid movement, the valve opening is blocked, thus preventing any flow of fluid and therefore any relative movement of the structures to which the connector is fixed.

Tests under alternated dynamic stresses

Behaviour in normal operation

Behaviour during a seismic event

Thanks to their tried and tested technology, the TRANSPEC® SHT connectors react immediately to rapid movements. Tests have shown their efficiency. The movements recorded correspond to the elastic deformation of the connector and remain limited to a few millimetres. However, for some projects, it would be better to have a greater elastic reserve, TRANSPEC® SHT connectors are adapted for this.

TRANSPEC® SHT connectors are installed at the end of the deck, as the horizontal forces are absorbed only by the abutment walls, or even at the pierheads, so as to distribute the loads to several bearing points. As well as the TRANSPEC® SHT Standard, FREYSSINET has developed TRANSPEC® SHT Compact to be installed directly at the top of a pier. The operational layout is the same as for the standard model.

Placing on the pier head in the context of retrofitting (Hambrook bridge, UK)

Positive protection: Dissipation

Un-dampened structure ———
Dampened structure ———

Dampers

Dampers are energy absorption devices which are able to limit both the movements and the loads to which the structures are subjected during an earthquake.

The dissipation of energy can be achieved using different means:

- Elastoplastic action
- Mechanical friction
- Viscous friction.

Viscous dampers are the most efficient.

TRANSPEC® SHA
Orival footbridge, Belgium

TRANSPEC® SHA hydraulic damper

Freyssinet has developed the TRANSPEC® SHA family of hydraulic dampers, which are used to protect any civil engineering or industrial construction exposed to seismic risk.

The TRANSPEC® SHA damper can be combined with isolators. It has a low resistance to slow relative movement of structures in normal service and actively reacts when they are subjected to rapid dynamic movements above a pre-set level.

The TRANSPEC® SHA is a hydraulic damper which uses a viscous oil whose characteristics are constant under temperature variations and with time.

The TRANSPEC® SHA damper is almost identical to the TRANSPEC® SHT connectors in the standard and compact version, the difference being that it has a patented oil flow servo-system mechanism which allows it to optimise the amount of energy absorbed depending on the movement. Its overall dimensions are the same as those of the connectors.

Model	Nominal force (kN)	Average length L (mm)	Body diameter Ø D (mm)	Height Plate A (mm)	Width Plate B (mm)
SHA 200-100	200	820	106	150	100
SHA 300-100	300	895	125	170	120
SHA 500-100	500	985	140	200	170
SHA 1000-100	1000	1235	210	260	200
SHA 1500-100	1500	1415	245	330	240
SHA 2000-100	2000	1565	290	390	300
SHA 3000-100	3000	1875	355	420	380
SHA 4000-100	4000	2110	405	490	490

Dimensions of the TRANSPEC® SHA standard with a stroke of 100 mm

The TRANSPEC® SHA damper is peculiar in that it has a nil internal pressure in service. This property offers the following advantages:

- Guarantees the efficiency of the damper during an earthquake as its efficiency is not related to the existence of an initial internal pressure which is uncertain to be maintained over time,
- Exceptional service-life of the gaskets and non-stressed mechanical parts.

The TRANSPEC® SHA also has an internal compensation chamber which allows to take into account the variations in oil volume when the temperature changes.

Freyssinet has extended its range of dampers to the TRANSPEC® SHA LC, which is intended for major movements (dampers placed on abutment). Using a special layout of the internal chambers, these dampers only function with the rod in tension, thus eliminating the risk of buckling whatever the direction of the force/movement.

Damper tests TRANSPEC® SHA

TRANSPEC® SHA dampers have been the subject of many fatigue tests which have backed up the technical and technological options adopted by Freyssinet.

As with the connectors, the dampers can be installed either at the end of the deck or at the top of the column.

Damper test
TRANSPEC® SHA

Positive protection: Dissipation of Energy

Elastoplastic damper

Principle of coiling

In some cases, TRANSPEC®SHA hydraulic dampers are unnecessary and the use of elastoplastic dampers, which take advantage of the hysteretic character of the plastic deformation of steel to dissipate the energy, can be considered.

In contrast to traditional elastoplastic dampers, whose performance is limited particularly in movement terms, the coiled dampers offered by Freyssinet (patented system) use a steel section supported by two circular templates. This allows to control the flexural stresses thus preventing any localised rupture and increases the volume of plasticised steel.

This device also functions as a spring for deformations within the elastic limit of the material.

As the elastoplastic dampers are small they can be connected to TETRON® CD cylinder structural bearings to form the compact DYNAROLL® assembly.

This extremely simple assembly reduces the lateral forces from earthquakes or fenders on the columns and foundations.

Furthermore, these robust devices need no special maintenance. The plasticised parts should however be changed after a high-intensity earthquake.

Configuration type

Fixed elastic TETRON®CD

Guided sliding elastic TETRON®CD

Choice of Protection

Bearing in mind the diversity of projects, Freyssinet suggests that the specification sheet below is completed. On the basis of the information supplied the Freyssinet engineers will assess the problem and design the most suitable equipment.

In addition, using the information supplied on the structure to be protected (mass, rigidity and principal dimensions, type: bridge or building) and the seismic conditions of the site, Freyssinet will be able to advise the designers on the most suitable seismic protection system to be adopted from the many solutions offered by Freyssinet.
